ANALOG DEVICES

Audio Switching Amplifier
AD1992

FEATURES

Integrated stereo modulator and power stage
<0.002% THD + N
102 dB dynamic range (A-weighted)
2 × 10 W output power (4 Ω, <0.01% THD + N)
R_{DS-ON} < 0.3 Ω (per transistor)
PSRR > 65 dB
On-off-mute pop noise suppression
EMI optimized modulator
Short-circuit protection
Overtemperature protection
Low cost DMOS process

APPLICATIONS

Advanced televisions
Compact multimedia systems
Minicomponents

GENERAL DESCRIPTION

The AD1992 is a 2-channel, bridge tied load (BTL), switching audio power amplifier with integrated Σ-Δ modulator. The modulator accepts a single-ended, analog input signal and converts it to a switching waveform to drive speakers directly. A digital, microprocessor-compatible interface provides control of reset, mute, and PGA gain, as well as feedback signals for thermal and overcurrent error conditions. The output stage can operate over a power supply voltages range of 8 V to 20 V. The analog modulator and digital logic operate from a 5 V supply.

Thermal Resistance	
θ_{JA}	19.2°C/W
θ_{JC} (at the Exposed Pad Surface)	0.9°C/W
θ_{JB} (on JEDEC Standard PCB)	9.7°C/W

[1] Including any induced voltage due to inductive load.

Stresses above those listed under Absolute Maximum Ratings may cause permanent damage to the device. This is a stress rating only; functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

ESD CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although this product features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

# PIN CONFIGURATION AND FUNCTION DESCRIPTIONS

THEORY OF OPERATION

OVERVIEW

The AD1992 is a 2-channel, high performance, switching, audio power amplifier. Each of the two Σ-Δ modulators converts a single-ended analog input into a 2-level pulse stream that controls the differential, full H-bridge, power output stage. The combination of an Σ-Δ modulator and a switching power stage provides an inherently linear and efficient means of amplifying the entire range of audio frequencies. The AD1992 also offers warning and protection circuits for overcurrent and over-temperature conditions, as well as silent turn-on and turn-off transitions.

Σ–Δ MODULATOR

The AD1992 is a switching type, also known as a Class-D, audio power amplifier. This class of amplifiers maximizes efficiency by only using its power output devices in full-on or full-off states. While most Class-D amplifiers use some variation of pulse-width modulation (PWM), the AD1992 uses Σ-Δ modulation to determine the switching pattern of the output devices. This provides a number of important benefits. Σ-Δ modulators do not produce a sharp peak with many harmonics in the AM frequency band as pulse-width modulators (PWM) often do. In addition, the 1-bit quantizer produces excellent linearity across the full amplitude range.

Σ-Δ modulators require feedback to generate an error signal with respect to the input. The feedback voltages for the AD1992 modulators come from the outputs of the power devices and before the passive low-pass filters (see Figure 35). This compensates for nonlinear behavior in the power stage, such as nonoverlap time, mismatched rise and fall times, and propagation delays. It also reduces sensitivity to both dc and transient changes of the power supply voltage.

Σ-Δ modulators operate in discrete time. As with all time-quantized systems, the Nyquist frequency is equal to half of the sampling frequency and input signals above that point aliases back into the base band. The AD1992 sampling frequency (master clock) is equal to half the frequency of the input clock, approximately 6 MHz, so images only alias for input frequencies above approximately 3 MHz. This is far enough above the audio band that bandwidth and aliasing are not a problem in real applications.

The modulator has a noise shaping effect, and SNR is increased in the audio band by shifting the quantization noise upward in frequency. For a nominal input clock frequency of 12.288 MHz, the noise floor rises sharply above 20 kHz. The actual clock frequency used in an application circuit can deviate from this rate by as much as ±10%, and the corner frequency of the noise scales proportionally. The frequency at which the quantization noise dominates the output determines the amplifier's practical bandwidth.

$\overline{\text{MUTE}}$ AND $\overline{\text{RESET}}$

When power is applied and the $\overline{\text{RESET}}$ pin remains asserted, the AD1992 is in its lowest power consumption mode. The analog modulator is not running, and the power stage is tri-stated. On deasserting the $\overline{\text{RESET}}$ pin, the modulator begins a start-up sequence that includes initialization of the modulator, the protection circuits, and other functions.

Once the start-up sequence is complete, the amplifier is in a state in which the modulator is running, but the output stage is not driven. When $\overline{\text{MUTE}}$ is deasserted, the output is started using a soft-start sequence that avoids any audible pop or click noise in the output signal.

The output power transistors do not switch while $\overline{\text{MUTE}}$ remains asserted. Unlike the analog mute circuits found on some amplifiers that can be limited in their attenuation by the control logic or crosstalk, the mute attenuation on the AD1992 is greater than its dynamic range. The noise floor of the output signal also drops while in $\overline{\text{MUTE}}$ because the output transistors are not switching.

Power-Up Sequencing

Careful power-up is necessary when using the AD1992 to ensure correct operation and to avoid possible latch-up issues. The AD1992 should be powered up with $\overline{\text{RESET}}$ and $\overline{\text{MUTE}}$ held low until all the power supplies have stabilized. Once the supplies have stabilized, bring the AD1992 out of $\overline{\text{RESET}}$ by bringing $\overline{\text{RESET}}$ high.

Begin the soft unmute sequence by bringing $\overline{\text{MUTE}}$ high at least 1 sec after the $\overline{\text{RESET}}$ rising edge. The amplifier produces audio using a shorter start-up sequence (as shown in Table 7), but the amplifier can produce an audible pop or click noise as the output starts switching. This is because the ac coupling capacitors at the analog input have a long time constant. If $\overline{\text{MUTE}}$ is deasserted substantially less than 1 sec after deasserting $\overline{\text{RESET}}$, then these capacitors may not have charged to a steady state. They need ample time to settle at a bias voltage of V_{REF}, the reference voltage for the single-ended inputs, or the amplifier starts with a slight dc offset.

GAIN STRUCTURE

Analog Input Levels

The AD1992 has single-ended inputs for the left and right channels. The analog input section uses an internal amplifier to bias the input signal to the reference level, V_{REF}, which is nominally equal to $AV_{DD}/2$. A dc-blocking capacitor, as shown in Figure 34, prevents this bias voltage from affecting the signal source. In combination with the nominal 20 kΩ input impedance, the value of this capacitor should be large enough to produce a flat frequency response at the lowest input frequency of interest.

Note that the amplifier is capable of dc-coupled operation if the circuit includes some means to account for this bias voltage.

Figure 34. AC-Coupled Input Signal

Setting the Modulator Gain

The AD1992 modulator uses a combination of the input signal and feedback from the power output stage to calculate its two-state output pattern. The feedback input nodes are part of the internal analog circuit that operates from the AV_{DD} (nominal 5 V) power supply. Because the voltage measured at the power outputs is nominally between 0 V and PV_{DD}, and thus beyond the 0 V to AV_{DD} range, a voltage divider is required to scale the feedback to an appropriate level.

Resistor voltage dividers should sense the voltage on each side of the differential output and provide these feedback signals to the modulator, as shown in Figure 35.

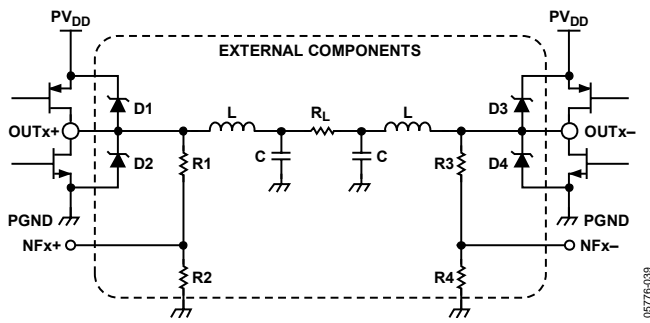

Figure 35. H-Bridge Configuration

The resistor values should satisfy the following equation to maintain modulator stability.

$$Gain = \frac{R1 + R2}{R2} = \frac{R3 + R4}{R4} = \frac{PV_{DD}}{3.635}$$

Selecting a gain that meets this criterion ensures that the modulator remains in a stable operating condition.

The ratio of the resistances sets the gain rather than the absolute values. However, the dividers provide a path from the high voltage supply to ground; therefore, the values should be large enough to produce negligible loss due to quiescent current.

The chip contains a calibration circuit to minimize voltage offsets at the speaker, which helps to minimize clicks and pops when muting or unmuting. Optimal performance is achieved for the offset calibration circuit when the feedback divider resistors sum to 6 kΩ, that is, (R1 + R2) = 6 kΩ, and (R3 + R4) = 6 kΩ.

This fixed total resistance to ground eliminates the last free variable and gives the following equations for the resistors:

$$R2 = R4 = \frac{21810}{PV_{DD}}$$

$$R1 = R3 = 6000 - R2$$

Note that the gain previously mentioned applies to each side of the differential output pair. Therefore, the total forward gain for the modulator and output stage is twice that value. Recommended resistor values for some common supply voltages are shown in Table 10.

Table 10. Recommended Feedback Resistor Values

PV_{DD} (V)	R1 (kΩ)	R2 (kΩ)	Voltage Divider Gain	Differential System Gain
12	4.18	1.82	3.30	6.60 (16.4 dB)
15	4.55	1.45	4.13	8.25 (18.3 dB)
18	4.79	1.21	4.95	9.90 (19.9 dB)
20	4.91	1.09	5.50	11.0 (20.8 dB)

Programmable Gain Amplifier (PGA)

The Σ-Δ modulator itself requires a fixed gain for a given value of PV_{DD} to maintain optimal stability. This gain can be appropriate, but many applications require more gain to account for low source signal levels. The AD1992 includes a programmable gain amplifier (PGA) to boost the overall amplifier gain. The total gain for the amplifier is the product of the modulator gain and the PGA gain. PGA1 (Pin 31) and PGA0 (Pin 32) select one of four PGA gain values, as shown in Table 11.

Table 11. PGA Gain Settings

PGA1	PGA0	PGA Gain
0	0	1 (0 dB)
0	1	2 (6 dB)
1	0	4 (12 dB)
1	1	8 (18 dB)

The AD1992 incorporates a single-ended-to-differential converter for each channel in the analog front-end section. The PGA is also part of this analog front-end, and it affects the analog input signal before it enters the Σ-Δ modulator. The PGA1 and PGA0 pins are continuously monitored and allow the gain to be changed at any time.

POWER STAGE

The H-Bridge

The output stage of the AD1992 includes four integrated MOSFET devices arranged in a full H-bridge, as shown in Figure 35. The P-Type, high-side transistor of one leg and the N-Type, low-side transistor of the opposite leg switch on and off as a pair producing a total voltage swing across the load of $-PV_{DD}$ to $+PV_{DD}$. The drive is floating and differential, and it is important that neither output terminal be shorted to ground.

The power supply for the output stage of the AD1992, PV_{DD}, should be in the 8 V to 20 V range and should be capable of supplying enough current to drive the load. Connect the power supply across the PVDD and PGND pins. The feedback pins, NFR+, NFR−, NFL+, and NFL−, supply negative feedback to the modulator as described in the Setting the Modulator Gain section.

For reactive loads, the impedance can only be below the recommended threshold over a small portion of the amplifier's bandwidth. In these cases, the amplifier can enter overcurrent shutdown in response to even small input signals in those frequency bands. When designing a system, use the minimum load impedance over the entire range of amplified frequencies when calculating current output rather than the average or nominal load impedance ratings often cited by loudspeaker driver manufacturers.

Output Transistor Nonoverlap Time

The AD1992 allows the user to select from one of eight different nonoverlap times, as shown in Figure 36. Nonoverlap time prevents or minimizes the period during which both the high-side and low-side devices are on simultaneously due to propagation delays and nonzero rise and fall times. If both the upper and lower portions of a half-bridge conduct simultaneously, there is a path directly from the power supply to ground and an induced current flow known as shoot-through. However, introducing this delay increases distortion by pushing the switching pattern further from an ideal two-state waveform. Selecting the nonoverlap delay requires a compromise between distortion and efficiency. The logic levels on the three delay control pins, DCTRL2, DCTRL1, and DCTRL0, set the nonoverlap time according to Table 12. The state of DCTRL[2:0] is read on the rising edge of $\overline{RESET}$ and should not be changed while $\overline{RESET}$ is logic high.

Table 12. Nonoverlap Time Settings

| DCTRL2	DCTRL1	DCTRL0	Nonoverlap Time (ns)[1]
0	0	0	62
0	0	1	49
0	1	0	37
0	1	1	24
1	0	0	15
1	0	1	13.5
1	1	0	12
1	1	1	9

[1] Values are typical and are not production tested.

Figure 36. Half-Bridge Nonoverlap Delay Timing

The shortest setting (DCTRL[2:0] = 111) or the second shortest setting (DCTRL[2:0] = 111) is recommended for most applications. These two settings allow a small trade-off between efficiency and distortion. Longer nonoverlap times generally increase distortion while providing little or no decrease in shoot-through current.

CLOCKING

The AD1992 Σ-Δ modulator requires an external clock source with a nominal frequency of 12.288 MHz. This clock can come from a crystal or from an existing clock signal in the application circuit. The discrete time portions of the modulator run internally at 6.144 MHz, corresponding to $128 \times f_S$, where f_S = 48 kHz.

As mentioned in the Σ-Δ Modulator section, the modulator has a noise-shaping effect such that SNR is increased within the audio band by shifting modulator quantization noise upward in frequency. For an external clock frequency of 12.288 MHz, the modulator's noise-shaping works in a manner that results in a flat noise floor at the amplifier output for frequencies 20 kHz and below. Above 20 kHz, the amplifier noise rises due to the spectral shaping of the modulator quantization noise. At very high frequencies, the noise floor levels off and decreases due to poles in the modulator noise-transfer function and in the external LC filter.

The clock frequency does not have to be exactly equal to 12.288 kHz and can vary by up to ±10%. For other rates, the noise corner scales linearly with frequency. When the modulator runs at a rate lower than nominal, the average power stage switching frequency decreases, the efficiency increases slightly, and the noise floor begins to rise at a slightly lower frequency. Likewise, a faster clock gives slightly increased bandwidth and slightly lower efficiency.

Using a Crystal Oscillator

The AD1992 can use a crystal connected to the CLKI and CLKO pins as a master clock source, as shown in Figure 37. The CLKI and CLKO pins connect to an internal inverter to create a full resonator. The typical values shown work in many applications, but the crystal manufacturer should provide the exact type and value of the capacitors and the resistor.

Figure 37. Crystal Connection

Using an External Clock Source

If a clock signal of the appropriate frequency already exists in the application circuit, connect it directly to CLKI and leave CLKO floating. The logic levels of the square wave should be compatible with those defined in Specifications section.

Large amounts of jitter on the clock input degrade performance. Whenever possible, avoid passing the clock signal through programmable logic and other circuits with unknown or variable propagation delay. In general, clock signals suitable for audio ADCs or DACs are also appropriate for use with the AD1992.

Clocking Multiple Amplifiers in Parallel

If there are multiple AD199x family amplifiers connected to the same PV_{DD} supply, use the same clock source (or synchronous derivatives) for each amplifier as previously described. Avoid clocking amplifiers from similar but asynchronous clocks if they use the same power supply because this can result in beat frequencies.

PROTECTION CIRCUITS AND ERROR REPORTING

Thermal Protection

The AD1992 features thermal protection. When the die temperature exceeds approximately 135°C, the thermal warning error output ($\overline{ERR1}$) is asserted. If the die temperature exceeds approximately 150°C, the thermal shutdown error output ($\overline{ERR2}$) is asserted. If this occurs, the part shuts down to prevent damage to the part. When the die temperature drops below approximately 120°C, the part returns to normal operation automatically and negates both error outputs.

Overcurrent Protection

The AD1992 features over current or short-circuit protection. If the current through any power transistors exceeds approximately 4 A, the part enters a mute state and the overcurrent error output ($\overline{ERR0}$) is asserted. This is a latched error and does not clear automatically. Restore normal operation and clear the error condition by either asserting and then negating $\overline{RESET}$ or by asserting and then negating $\overline{MUTE}$.
